**SUMMARY**

Tungsten fiber reinforced niobium metal matrix composites were evaluated for use in space nuclear power conversion systems. The composite panels were fabricated using the arc-spray monotape technique at the NASA Lewis Research Center. The creep behavior of W/Nb composite material was determined at 1400 and 1500 K in vacuum over a wide range of applied loads. The time to reach 1% strain, the time to rupture, and the minimum creep rate were measured. The W/Nb composites exceeded the properties of monolithic niobium alloys significantly even when compared on a strength to density basis. The effect of fiber orientation on the creep strength also was evaluated. Kirkendall void formation was observed at the fiber/matrix interface; the void distribution differed depending on the fiber orientation relative to the stress axis. A relationship was found between the fiber orientation and the creep strength.

## INTRODUCTION

Advanced materials will play a major role in meeting the stringent size and performance requirements of future space power systems. The requirements for such a system, which may include a service life of greater than 7 years at a temperature in excess of 1350 K, in addition to resistance to liquid metal corrosion, dictate the use of refractory metals. Currently, monolithic niobium-based alloys are specified for components in the power conversion system of space nuclear power systems. These include the niobium-1% zirconium alloy (Nb-1Zr) and the PWC-11 alloy (Nb-1Zr-0.1C). Tungsten fiber reinforced niobium metal matrix composites (W/Nb) are being considered for future applications in this area where higher temperature and higher stress conditions may exist. W/Nb composites offer potential for high tensile and creep strength applications up to 1700 K (Westfall et al 1986; Petrasek and Titran 1988).

One challenge to overcome in using these composites is the possible degradation in properties at long times due to interdiffusion between the fibers and matrix. Interdiffusion between tungsten and niobium results in a continuous solid solution and therefore would not be a catastrophic process, as it would be if a brittle intermetallic phase were formed. Interdiffusion may, however, cause recrystallization of the tungsten fibers which would reduce the strength of these fibers. The projected life (greater than 60 000 h) and temperature requirements (up to 1700 K) could therefore result in a reduction in creep strength of the W/Nb composite (Grobstein 1989).

## MATERIALS AND PROCEDURE

The strength to density ratio of several tungsten-based wires compared to the Nb-1Zr alloy is plotted in Figure 1. Each of these wires has the potential for fiber reinforcement of the Nb-1Zr matrix due to their high strength. The weakest wire shown here is the 218CS wire, a potassium-doped commercially available lamp filament. The ST300 wire contains a fine dispersion of 1.5 w% ThO<sub>2</sub>, about 1  $\mu$ m in size. The strongest wire contains an even finer dispersion of HfC particles. Photomicrographs of these three types of wire are shown in Figure 2. Unfortunately, the WHfC wire is not currently available, so the ST300 wire, with a diameter of 200  $\mu$ m, was chosen for the reinforcement material.

The matrix materials were niobium and niobium with 1% zirconium. The addition of 1% zirconium to niobium results in zirconia precipitates which strengthen the alloy and removes oxygen from the grain boundaries of the niobium, which is important for lithium corrosion resistance. Niobium was chosen as a matrix material only for comparison purposes.

These composites were fabricated by the Lewis-patented arc-spray monotape technique (Westfall 1985). This process, schematized in Figure 3, consists of wrapping the reinforcing fibers on a drum, placing the drum in an air-tight chamber, evacuating the chamber, and back-filling it with argon. Next, two wires of the matrix composition are brought together in the arc-spray gun, an arc is struck between them, and pressurized argon blows the molten matrix material onto the reinforcing fibers. The drum rotates until all the fibers are covered; the resulting structure is a "monotape" consisting of one layer of fibers in a matrix (Figure 4). Layers of monotapes then can be hot pressed

or hot isostatically pressed (HIP), producing a fully densified consolidated structure with negligible fiber/matrix interfacial reaction (Figure 5). Composites panels can be fabricated with a wide range of fiber volume fractions and angle plies using this technique. In addition, tubing is easily made using monotapes (Figure 6).

Composites panels were fabricated having ~30 to 54 volume percent fibers. For comparison purposes, applied creep stresses were normalized to 50 volume percent using the equation,

$$\frac{\sigma_{app}}{v\%} = \frac{\sigma_{norm}}{50v\%}$$

Creep specimens having a gauge section 25 mm long and 6.35 mm wide were then electric discharge machined from the composite panels (Figure 7). The fibers in the specimens were oriented unidirectionally either parallel or perpendicular to the longitudinal specimen axis. Some specimens also were fabricated with fibers angle-plyed  $\pm 15^\circ$  to the longitudinal axis, as shown in Figure 8.

Creep-rupture tests were conducted in a vacuum of  $7 \times 10^{-5}$  MPa. Creep strains were measured optically via a cathetometer clamped to the furnace chamber frame sighting on Knoop hardness impressions placed 25 mm apart on the gauge length. The precision of creep strain measurements was estimated to be ~0.02% for the gauge length used. The strain on loading was measured and was incorporated in the reported total creep strain. Creep rupture data was obtained at 1400 and 1500 K.

## RESULTS AND DISCUSSION

The fiber/matrix interfacial reaction was examined by metallographically polishing transverse sections of creep specimens. Figure 9a shows a ST300/Nb-1Zr composite which was under stress at 1500 K for ~2550 h. The distinct reaction zone appears to be a result of interdiffusion between the fiber and matrix. In the case shown in Figure 9a, the reaction zone was ~10  $\mu\text{m}$  in width, resulting in approximately a 20% decrease in the unaffected fiber area. Figure 9b shows a ST300/Nb-1Zr specimen tested at 1500 K for ~5353 h. In this case, the reaction zone increased to ~15  $\mu\text{m}$  in width, a 28% decrease in the unaffected fiber area. (These values are for 200  $\mu\text{m}$  diameter fibers; the percentages would increase for smaller diameter fibers and decrease for larger ones.) The measured reaction zone width for these long-term exposure samples agrees with that predicted by measuring the reaction in specimens exposed for shorter times.

Typical fracture surfaces are shown in Figure 10. The reaction zone was more extensive for specimens exposed for the longer times, as was the porosity in the matrix. No difference was apparent in the fracture ductility for the conditions shown, although some evidence of matrix oxidation was evident in samples exposed for over 5000 h.

The rupture time versus the normalized applied stress is plotted in Figure 11, and Figure 12 shows the minimum creep rates plotted versus the

normalized stress. Again, the longer-term creep data obtained in this study validate predictions made based on previous shorter-term data (Petrasek and Titran 1988).

Microhardness measurements across the interfacial region shown in Figure 13 reveal that the properties of the zone are between that of the fiber and the matrix. In specimens exposed for long times, oxidation appeared to increase the hardness of the matrix somewhat.

Figure 14 displays the rupture strength of the composite at 1500 K as the fiber orientation is varied from 0 to 90° with respect to the stress axis. Composite specimens with a 0° fiber orientation are obviously the strongest, whereas those with a 90° orientation are the weakest. The creep fracture morphology of the transverse specimens (90°) specimens indicated that failure occurred in the matrix rather than due to cleavage of the fibers or debonding between the fiber and the matrix.

Interdiffusion between tungsten and niobium forms a binary solid solution (Shunk 1969). However, the rate at which the two types of atoms diffuse is not the same. Experimental measurements have shown that the element with the lower melting point diffuses faster (Reed-Hill 1973). Thus, in this system, the niobium will diffuse into the tungsten fiber faster than tungsten diffuses out into the matrix. After extended exposure at temperature, the niobium matrix will suffer a loss of mass because it loses more atoms than it gains, while the tungsten gains in mass. This is called the Kirkendall effect. As a result of this mass transfer, the fiber wants to expand and the matrix wants

to shrink, but these dimensional changes are resisted by the bulk of the metal that lies outside the diffusion zone. The matrix is therefore placed under a tensile stress, and the fiber under a compressive stress. These stress fields may bring about plastic flow, with the resulting structural changes normally associated with plastic deformation and high temperatures; formation of substructures, recrystallization, and grain growth.

The interdiffusion therefore results in a recrystallized and tungsten-depleted area within the original fiber diameter. Since drawn tungsten fibers have been shown to have as high as five times the strength of recrystallized tungsten due to their fibrous grain structure (Yih and Wang 1979), this recrystallized interdiffusion zone may adversely affect the composite properties.

In addition to the effects listed above, the disparity in diffusion rates may cause Kirkendall void formation. Since there is a net vacancy flow in one direction, voids may form in the region of the diffusion zone from which there is a flow of mass. In the composite, this is just outside the fiber diameter. These type of voids are shown in Figure 15a. It should be noted that void formation may be influenced by necking of the fibers at failure, which will cause the fiber to pull away from the matrix. These tensile stresses and those due to mass flow are a contributing factor in the development of voids. Barnes and Mazey (1958) found that if this tensile stress is counteracted by a hydrostatic compressive stress placed on the sample, the voids can be prevented from forming.

Suppression of the void formation is observed in  $\pm 15^\circ$  angle-ply composites in some areas around the fiber in Figure 15b. Compressive stresses are present parallel to the long transverse direction (vertical in this micrograph), so the Kirkendall voids form only in the unaffected areas. Similarly, void formation should be accelerated in specimens with transversely oriented fibers, although this was not observed in samples tested up to 800 h. Although the effect of fiber/matrix interdiffusion on properties does not appear to be significant from the results presented here, it is not yet fully understood. Consequently, the apparent loss in creep strength of samples with the longest times to rupture (Figures 11 and 12) was attributed to oxidation of the matrix rather than to interdiffusion zone effects.

Figure 16 compares the time to 1% strain of unidirectionally reinforced composites to ST300/Nb angle-ply composites, monolithic commercial Nb-1Zr, and the PWC-11 alloy (Nb-1Zr-0.1C). Composites with  $\pm 15^\circ$  angle-ply fibers were ~20% weaker, but exhibited approximately the same stress exponent as the unidirectionally reinforced panels, indicating that the same creep mechanisms were at work. It is seen in this figure that the properties of even those panels with  $\pm 15^\circ$  angle-ply fibers exceeded the creep properties of the monolithic PWC-11 alloy by a factor of four and the Nb-1Zr alloy by an order of magnitude.

## CONCLUSIONS

1. The results presented here indicate that W/Nb composites have good potential for use in space power systems.

2. Angle-plying the reinforcing fibers has the potential to increase the transverse strength of the composite.
3. Interdiffusion between tungsten and niobium did not appear to significantly degrade the creep strength of the composite at times up to 5000 h.
4. The creep properties of W/Nb composites at 1500 K significantly exceeded those of monolithic niobium alloys even when compared on a strength to density basis.

#### Acknowledgments

Discussions with RH Titran and DW Petrusek were indispensable to the completion of this study. Expert metallography by TA Leonhardt is also gratefully acknowledged. This work was performed by the NASA Lewis Research Center for NASA and the Strategic Defense Initiative Office under an interagency agreement entered into in October 1985.
